

Fundamental Aspects of Cognitive Representation

Stephen E. Palmer
University of California, Berkeley

a scientific field with a deep understanding of its problem, much less its solution. multidimensional spaces, templates, features, structural descriptions, relational sitional representations, first-order isomorphisms, second-order isomorphisms, poorly defined, and embarrassingly disorganized. Among the most populativering representation. The rationale is that a solution is more likely to be achieved if ferent ways and different terms in the same way. These are not characteristics of are not clear and do not fit together. Different people use the same term in diftions were clear and if they fit together in a systematic way. The fact is that they guage for talking about representation would be a good thing if all the distincnetworks, multicomponent vectors, and even holograms. This abundance of lanname codes, image codes, analog representations, digital representations, propoone finds the following: visual codes, verbal codes, spatial codes, physical codes, tion quickly becomes confused - and with good reason. The field is obtuse. Anyone who has attempted to read the literature related to cognitive representasupport of them, but we do not understand them in any fundamental sense pose them, talk about them, argue about them, and try to obtain evidence in psychologists, do not really understand our concepts of representation. We prothe problem is understood properly. This chapter is an extended inquiry into the nature of the problem of cognitive This chapter was born of an ill-defined but definite feeling that we, as cognitive

In order to make systematic progress on problems concerning cognitive representation, we must begin at the beginning; What is representation? This is a question few psychologists have ever asked and even fewer have made any serious attempt to answer. It is so basic a question that one might wonder whether its answer would be of any value to cognitive psychology. It is the main thesis of this chapter that the answer is enormously important and will change our under-

standing of both theories and experiments concerned with cognitive represen-

people's internal representations of the world. That is, we want to construct clear having a theory of) what representation is will help us in either the theoretical or acterization of the situation, is there any reason to believe that knowing (or questions delineate the nature of an adequate theory. If this is a reasonable charconcise theories of cognitive representation that can be evaluated using the experimental enterprise? tion is to ask questions by experimental hypothesis testing. The answers to these methods of psychology as a behavioral science. The standard method of evalua-Let us assume that our goal is to specify as clearly as possible the nature of

empirical tests, and her description is simpler and more specific to the relevant particular specimen. When he is done, his description might be that oaks are obing characteristics of oaks, but these are mixed together with properties that are count the number of branches on this particular tree, because she knows this to knowing something about the general nature of trees. She is able to make fewer relevant only to treeness and with other properties that are relevant only to this measurements than A. If he is diligent enough, he eventually discovers the definproperties a, b, and c. Botanist B, however, necessarily performs many more be irrelevant to her task. When she is done, she describes oaks as, say, trees with because she knows that all trees have these attributes. Nor does she bother to characteristics of oak trees by performing a series of tests on a given specimen. jects with properties a, b, c, d, Obviously, A has an advantage over B in knows none of these things. Botanist A works quickly and efficiently. She makes to classification, and how they differ in ways that are irrelevant. Botanist B teristics are, how types of trees differ from one another in ways that are relevant Botanist A has a thoroughgoing knowledge of trees: what their defining characobjects. Suppose there are two botanists whose task is to describe the essential ing about representation as a general construct is much like trying to determine those measurements. She does not bother to note that oaks have bark and leaves the measurements necessary to describe oaks versus other types of trees and only the nature of oak trees without first knowing about trees as a general class of Trying to determine the nature of cognitive representation without first know

theoretical and experimental enterprises are meaningful at all. In short, the anical descriptions and separates essential aspects from nonessential ones. In fact, are deemed important and relevant. a representational metatheory. As far as I can tell, the present framework for ask in our experiments. Ultimately, this boils down to asking whether our current the psychological literature. The issue is whether these are sensible questions to experiments that purport to test these alternatives. Such experiments abound in plates, features, structural descriptions, and so forth. Therefore, psychologists do tional theories are defined by descriptive terms like those mentioned earlier: temrepresentations is a loose system of distinctions and classifications. Representaframework for representation is sensible. If this is so, then we must currently have something that serves the function of

ever, lead to conclusive results. There always seem to be ready explanations from exclusive at a level that is meaningful for our goals and methods. to complications such as processing differences, because both representation and the allegedly discredited theoretical position. This fact can be partially ascribed to experimental psychologists — the empirical tests of such distinctions rarely, if understanding of the concepts themselves. Fourth - and perhaps most apparent Our inability to provide good answers to such questions is symptomatic of our something less than a proper definition. Part of the reason they have not been itly defined. We can point to some samples of each concept, but this ability is answer. Second, virtually none of the current distinctions have ever been explicthe problem is that many of the distinctions we purport to test are not mutually processing assumptions are required to predict performance. But often I suspect to the analog/propositional distinction? How do templates relate to prototypes? the template/feature distinction independent of, the same as, or otherwise related framework. (Third, the distinctions do not relate to each other systematically. Is defined is that good definitions are much easier to construct within a larger general. This is why the basic question — what is representation — is so hard to we make do not follow from or lead to any coherent view of representation in There are several observations suggesting that it is not First, the distinctions

sentation based explicitly on an answer to the general representational question. of the field. In the rest of this chapter, I propose a new view of cognitive reprewere tormerly puzzling and bring a more elegant and coherent view to the domain sults show that many of the mistakes we have made in understanding representa them are clarified, and relevant aspects are separated from irrelevant ones. The retions, prototypes, isomorphisms, propositions, and analogs. Relationships among definitions are provided for constructs like templates, features, structural descrip tion. It is then applied to the concepts of the older framework. As far as possible, to take its place. The new paradigm should be able to make sense of things that paradigm simply because it is seen to be defective. Rather, another must emerge tion are alarmingly fundamental. This view is developed informally with an emphasis on noncognitive representa-As Kuhn (1962) has noted, a scientific discipline does not abandon a reigning

REPRESENTATIONAL METATHEORY

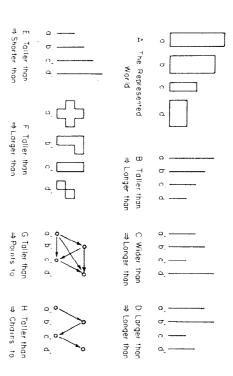

complex ones so that the basic issues are clear from the outset. simple and easy to study. The plan is to move from simple representations to is exceedingly complex and difficult to study. Other sorts of representations are real or artificially constructed for this particular purpose. Cognitive representation is how to attack this question without considering cognitive representation itself The answer, of course, is to examine noncognitive forms of representation, either Let us turn now to the basic question: What is representation? The first problem

Some Examples of Representation

are doing the modeling; and (5) what are the correspondences between the two worlds. A representation is really a representational system that includes all five represented world are being modeled; (4) what aspects of the representing world presented world is; (2) what the representing world is; (3) what aspects of the must be some corresponding aspects if one world is to represent the other. In orsenting world need to model an aspect of the represented world. However, there der to specify a representation completely, then, one must state: (1) what the reaspects of the represented world need to be modeled; not all aspects of the repre-A representation is, first and foremost, something that stands for something else. world is to reflect some aspects of the represented world in some fashion. Not all the represented world and the representing world. The job of the representing description implies the existence of two related but functionally separate worlds: In other words, it is some sort of model of the thing (or things) it represents. This

ing relative length in B as long as the mapping of rectangles to lines were known. tive height of rectangles in A." The implication is that any question that could be could describe this representational system by saying, "World B is a representaof rectangles in World A and the corresponding lines in World B. It is always true angles (a, b, c, d) by the relative length of the corresponding lines (a', b', c', d'). and D show how different aspects of the same represented world can be modeled answered about relative height in A could be equally well answered by considertion of World A in which the relative length of lines in B corresponds to the relathat if x is taller than y in World A, then x' is longer than y' in World B. One that a' is longer than b' in World B. Similar statements can be made for any pair In other words, the fact that a is taller than b in World A is reflected by the fact by the same representing world. World B reflects the relative height of the rectaspects that could be modeled in a representation. The representing Worlds B, C rectangles shown in Fig. 9.1A. These drawings, simple as they are, contain many trate the previous points. In all cases, the represented world is the set of four Figure 9.1 shows some simple examples of representational systems that illus

formation, however, it is clear that they are quite different between the two worlds, representations B, C, and D are identical. Given this inknowledge of the represented world, its modeled aspects, and the correspondence sentation simply by pointing to a representing world of objects. Without angles in World A. These examples demonstrate that one cannot specify a repreperforms the same kind of representational function for relative size of the rectis reflected in the fact that d' is longer than any other line in World C. World D

model the represented relation ("taller"). of B only in that a different relation ("shorter" rather than "longer") is used to the rectangle, the shorter the line. This representational system differs from that rectangles in terms of line length; the taller the rectangle, the longer the line. World E also models rectangle height in terms of line length; but here, the taller can be modeled using different representing worlds. World B models height of Worlds B, E, F, G, and Hillustrate how the same aspect of a represented world

irrelevant to its modeling function. tion to using a different relation to represent "taller than," this example illustrates that there may be other aspects of the representing world that are forms. Note that object shape has no correlate in the represented world. In addi-World F reflects the height of rectangles by the size (area) of closed geometric

pointing to b' in G. What makes this kind of representation different from those the rectangles in Λ . Here, the fact that a is taller than b in Λ is reflected in a'discussed previously is that: (1) the representing objects corresponding to the World G embodies a rather different way of preserving height relations among

saying that B represents relations ("taller than") by relations ("longer than") element (the relational arrow) in a particular way. ordered pair of objects, "is arrow-connected to" is a relation that can hold benected to") in World G is a relation just as "longer than" is in World B. The while G represents relations ("taller than") by elements (the arrows). The real tempting to characterize the difference between representations B and G by world does not correspond to any single object in the represented world. It is tional elements." That is, the presence of a given arrow in the representational tant to notice that the arrows of World G are not "object elements" but Felatween an ordered pair of objects only by virtue of each being related to a third difference is that although "longer than" is a relation that can hold between an difference is more subtle, however. "Points to" (more accurately, "is arrow-concorrespond explicitly to the relation being modeled ("taller than"). It is imporrectangles are identical; and (2) new elements (the arrows) have been added that

arrows, the resulting representation would be identical to World G. solution is to use the "chains to" relation (more accurately, "is arrow-path to see that if all the "chains to" relations were made explicit in World H by connected to"), which is essentially a transitive version of "points to." It is easy than" to be represented, the "points to" relation must be made transitive. The restricted relation that might be called "next-taller than." In order for "taller "taller than" relation in A. "Is arrow-connected to" models some other, more tains explicit relational elements, but the arrows are not sufficient to model the World H illustrates yet another type of representation. Like World G, it con-

same, but some are more similar than others. We examine these similarities and of this possibility. No two representational systems in Fig. 9.1 are exactly the reflect different information about the represented world. Worlds B, C, D, and information contained by the representing worlds can be the same yet can information that reflects some information about the world they represent. The differences in more detail shortly. formation about the represented world. Worlds B, E, F, G, and H are examples by the representing worlds can be quite different, yet can reflect the same in-E of Fig. 9.1 are examples of this situation. In contrast, the information contained intuitively, what all these representations have in common is that they contain

Operational Relations

ships between it and the world it represents. But the concept of representation certain purposes instead of the represented world. In order for this to happen, also includes an operational component. The representing world can be used for represented world that is also a "thing." It does so by virtue of certain relation briefly the interdependence of representation and its processing environment there must be processes to operate on the represented world. We now consider Thus far a representing world has been treated as a "thing" that stands for a

> lines, and other operations define the "chains to" relation in World H. operations for finding them and the circles they connect. The operations of findthat hold among the object elements. Consider World G of Fig. 9.1. The arrows in World B, some operations define the "longer than" relation between pairs of ing an arrow and its associated circles define the "points to" relation. Similarly, connecting the circles in the diagram are only meaningful and useful if there are operations in the present analysis is that they functionally determine the relations discuss representation without considering processes. The role of processing It is axiomatic within an information-processing framework that one cannot

operational concepts for these relations. In constructing processes to use these to," and "chains to." This works because we all have more or less the same interprets the length of lines — whatever they may be — such that corresponding what the processes do to determine whether or not a particular relation holds. representations, however, operational definitions must be specified in terms of "taller than" relation in the represented world. there is an operational relation defined by this process that corresponds to the lengths are functionally ordered just as the rectangle heights are ordered, then there is no intuitively obvious relationship (such as our usual concepts of "longer height of rectangles, for example, might be represented by line length where but is appropriate and sensible given the processes that operate upon it. The than" or "shorter than") to model "taller than." But if there is a process that It is possible to have a representation that seems nonsensical by intuitive notions In these cases, we relied on our intuitive notions of "longer than," "points

completely defined by the operations in both cases. but only that it is more intuitively obvious what the relationship is. "Next" is mean that "next" is any less operationally defined in the array-processing language defined such that it is also the next numerical address in memory. This does not processing language, the situation is different. The "next" element of an array is current element in terms of access order by the interpretive process. In an arrayby the current element. Thus the "next" element is functionally next to the defines the "next" element as the one "pointed to" (i.e., addressed indirectly) in memory or their numerical addresses. The list-processing language operationally of a list in list-processing computer languages. There is no necessary relationship between one element of a list and the next element in terms of physical location A more familiar example of the same general concept is the "next" element

shyn's "semantic interpretation function" is very similar to the present concept simply those defined by the processes that interpret the representation. [Pylyrelations, we implicitly include certain aspects of processing operations in the of operational relations (Pylyshyn, 1975).] Thus, in talking about operational operational relations rather than apparent relations. Operational relations are representation itself. Without those processes, the representation is meaningless. The importance of this argument is that the relations in a representation are

an important sense in which the only information contained in a representation The dependence of representation on processing goes even deeper. There is

computer, it is there even though it does not seem to be. contained in an ordinal matrix of this sort, but prior to Shepard's demonstration, scaling algorithm (and its descendants) is able to recover it from the original contains enough information to produce a reasonable approximation to a map there at all except for the computer programmed to extract it, and for that the represented information. No person or machine can derive it without actually knowing it is theoretically there is not sufficient for it to be considered part of this was not thought to be the case. More to the point, however, is that simply matrix. We now know that a great deal of locational information is implicitly containing those cities. The proof that such information exists is that Shepard's about distance and some information about direction as well. In fact, the matrix known until recently — is that this matrix contains a great deal more information relative distances between cities. What is not so obvious - indeed, what was not obvious to everyone that this representation contains weak information about is that for which operations are defined. In other words, it does not matter whether performing the operations. In short, the implicit locational information is not tables the ordinal distances among, say, 30 cities in the United States. It is world if there are no methods for doing so. A good example is Shepard's (1962a. certain relationships could, in principle, be derived from a given representing 1962b) multidimensional scaling procedure. Suppose there is a matrix that

tained in a representing world. The notion of operational relations changes the way we view our constructs of representation. In general, we must be very careful about deciding just what information is conbeen universally misunderstood precisely because this fact is not appreciated As we see later, the representational nature of several kinds of theories have obtain it. When stated in this way, the point seems almost trivial, but it is not tion contained in a representation is that for which operations are defined to This rather esoteric example illustrates a very simple fact. The only informa

The Nature of Representation

objects. Preserving information, then, is equivalent to having corresponding by relations that hold among them. These relations are operationally defined relations in the two worlds. tion contained in the two worlds is the set of operational relations among represented world. We can tie all of this together by assuming that the informationally separate worlds. Each world consists of objects that are characterized First, a representation requires a certain kind of relationship between two func-Let us stop now and consider what we have learned from the analysis thus far. The function of a representing world is to preserve information about the

such that at least some relations in the represented world are structurally preserved from objects in the represented world to objects in the representing world The nature of representation is that there exists a correspondence (mapping)

> requires that a corresponding relation, R', holds for each corresponding pair of ordered pairs of represented objects, $\langle x, y \rangle$, then the representational mapping in the representing world. In other words, if a represented relation, R, holds for "points to" relation in World G, and by the "chains to" relation in World H. than" relation in World E, by the "bigger than" relation in World F, by the World A is preserved by the "longer than" relation in World B, by the "shorter describing situations like those shown in Fig. 9.1. The "taller than" relation in representing objects, $\langle x', y' \rangle$. This is just a very abstract and general way of

corresponds to 2-feet-tallness. This fits our description of representation if we interchangeably. for sets of n objects). We use the terms "unary relations" and "properties" "binary" relations (defined for pairs of objects) or "n-ary" relations (defined relations (defined for individual objects) that are no different in principle from fact, this is just the way properties are modeled in set theory - as "unary" view properties of individual objects as relations that hold for single objects. In must correspond to objects in the representing world that have whatever property individual objects. All objects in the represented world that are, say, 2 feet tall The same sort of representational relationship can hold for properties of

one another in the way they relate to their respective represented worlds. Given our definition of representation, it is clear that two representations can differ sentations can differ in the objects they represent, we focus our attention or in the objects and/or the relations they represent. Having noted that two repre how two representations can differ when the objects they represent are the same tions can differ, then, is really a question about how two worlds can differ from world in relation to its represented world. The question of how two representadiffer from one another. A "representation" obviously refers to a representing Y. The second goal is to characterize the ways in which two representations can lations for objects of X are preserved by relations for corresponding objects of A world, X, is a representation of another world, Y, if at least some of the re-We now have at least an informal answer to the basic representational question

of relations, we call the latter situation informationally equivalent representation representation is concerned with preserving information, and information consists in different ways. This is the case in Worlds B, E, F, G, and H of Fig. 9.1. Because and D of Fig. 9.1. Second, two representations can model the same relations, but different relations of the represented objects. This is the case in Worlds B, C, major kinds of differences to consider. First, two representations can model If a pair of representations model the same set of objects, then there are two

set of objects and sets of relations. A representational system is an ordered triple con-Suppes & Zinnes, 1963). This formalization, however, is beyond the current level of disurement theory for numerical representation (Krantz et al., 1971; Scott & Suppes, 1958 objects into the representing objects. The basic approach is similar to that used in meas sisting of the two relational systems and a homomorphic function that maps the represented 1954). The represented and representing worlds are relational systems, each consisting of a ¹This definition has a straightforward formalization in terms of model theory (Tarski

completely equivalent representation. in which the same relations are modeled in the same way. This situation is called and the former nonequivalent representation. The only remaining cases are those

Nonequivalent Representations

could not answer the same questions about the represented objects from both other words, given two such representations and their processing systems, one representations. There are many possible differences that could result in this equivalent in the sense that they do not preserve the same information. In Two representations that reflect different relations of the same objects are not

ordered pair. Similarly, n-ary dimensions can be defined for larger sets of objects sions except that they can hold only for ordered pairs of objects. The distance simply the relations that comprise the dimension. Thus, "being two feet tall," because one-and-only-one of the component relations can hold between each between two objects and their relative sizes are examples of binary dimensions, height, color, and handedness. Binary dimensions are defined just as unary dimen-"being red." and "having a hand" are possible values for unary dimensions of dividual object has only one value for each. The "values" along a dimension are of objects on which the relations are defined. Properties of individual objects of mutually exclusive relations, only one of which is true for each object or set like height, length, size, and so forth are unary dimensions, because each intion in the represented world. For present purposes, a "dimension" is just a set that two representations can model qualitatively different dimensions of varia- e.g., the relative distance between an object and two others. Type of Information. The most obvious condition for nonequivalence is

important way in which two representations can differ, because they cannot because B represents relative height information whereas C does not, and C no information about that dimension. In other words, one world represents that much less the same specific questions. be used to answer the same kind of questions about the represented objects represents relative width information whereas B does not. Clearly, this is an dimension somehow, but the other does not. Worlds B and C are examples, tion about a given dimension, whereas the other representing world may preserve that one representing world may preserve some (but not necessarily all) informa-The intended notion of differences in type of information represented is

are two relations and an infinite number. Consider some possible representations just a few relations, whereas in another it may contain many. The limiting cases differ in many ways. The dimensional representation in one world may contain Resolution. If two representations model the same dimension, they can still

> sified as "long" in the two-valued system might fall in two different length which they provide different answers. For example, two objects both clascategories within the 100-valued system. These two representations are nonequivalent, because there are questions for in the first system that have different representations of length in the second 100 values. There will be many objects having the same representation of length of the length dimension. In one representation, all lengths are categorized into just two values: "short" or "long." In the other, they are categorized into, say

tional system. This possibility, however, is beyond our present level of inquiry. the m dimensional values for each object to construct a probabilistic representaministic, but it need not be. One could define a probability distribution over the assignment of relations (values along the dimension) is completely deterhigher the resolution and the finer the grain. We are presently assuming that resolution or grain. The larger the number of relations in a dimension, the number of relations comprising the dimension is one important aspect of its In general, any dimension can be described as containing m relations. The

to dot-size, the same city might be represented as a large dot in one map and a size to represent city-size. If they used different criteria for assigning city-size without those levels containing objects that correspond to the same objects in are preserved. Two representations might each have the same number of levels of levels but must classify the represented dimension in the same way. medium dot in the other. In order for the resolution of two representations to the represented world. Two maps, for example, might have three levels of dotbe identical for some dimension, then, they must not only have the same number The other aspect of resolution is concerned with the particular relations that

whether two cities are generally the same in size or different, but their order is sider two maps again with three levels for their representation of city-size. In same resolution, they can still be nonequivalent in the sense defined earlier. Conwhat is needed - an operational ordering relation for the colors. Without the size-to-color mapping, one can figure out the relative sizes. The key provides not necessarily represented. If there is a "key" on this map that indicates the to some extent. In the second map, this is not obviously true. One can tell sized dots. That is, the ordering of dot sizes preserves the ordering of city sizes one can tell which of two cities is the larger if they are represented as different represented as red, blue, and yellow dots of the same size. Using the first map that the larger the city, the larger the dot. In the other map, the cities are one map, the cities are represented as black dots of three different sizes such size of cities could be answered from the first map but not from the second key, however, the two maps are not equivalent, because questions about relative Uniqueness. If two representations represent the same dimension with the

because it is analogous to the concept of uniqueness in measurement theory We call this kind of difference the uniqueness of a dimensional representation

all current theories of language representation are exclusively nominal, and many Any dimension in which only identity is preserved is nominal. theories of perceptual representation contain substantial nominal components representations are so weak that they are uninteresting, but this is not so. Nearly after the similar case of measurement scales. It might be thought that nominal for pairs of dimensional values. This kind of representation is called nominal dimension are not functionally ordered, only same/different relations are defined (Krantz et al., 1971; Suppes & Zinnes, 1963). In the case where the levels of a

are meaningful; "different" relations of nominal dimensions are divided into as identity information. Such representations are called ordinal, after the corinformation than nominal ones in the sense that additional higher-order relations responding type of measurement scale. Ordinal representations preserve more "more" and "less" relations in ordinal dimensions. the represented objects are ordered, then order information is preserved as well If the relations of a dimension functionally order the representing objects as

representation as well if the correlates of numerical transformations can be numerical, these concepts are meaningful. Perhaps they are in other kinds of numerical representation (e.g., interval, ratio or absolute representations corresponding to those types of scales). Certainly, when the representation is identified. For present purposes, we simply note that such an analysis seems It is not clear how to describe other types of uniqueness properties for non

Informationally Equivalent Representations

same view of the world they represent. sentation differ should not obscure the fact that they provide essentially the same information in many different ways. The fact that their methods of repremean that the representations are identical, of course. They can preserve the of the information they preserve about the represented world. This does not called informationally equivalent, because they are indistinguishable in terms Two representations that preserve the same relations about the same objects are

can differ. These differences may be subtle (e.g., Worlds B and E of Fig. 9.1) all the possibilities. Rather, I focus on two distinctions that seem to be important or obvious (e.g., Worlds B and G of Fig. 9.1). No attempt is made here to catalog There are countless ways in which informationally equivalent representations

is taller than ν , and ν is taller than z, than it must be true that x is taller than zit cannot also be true that y is simultaneously taller than x. In the language of of rectangle height in Fig. 9.1A. Consider two facts about the nature of the represented relation "taller than." First, if an object x is taller than an object y, clearly exemplified by the contrast between Worlds B and G as representations logic, this fact defines "taller than" as an asymmetric relation. Second, if x Intrinsic Versus Extrinsic Representation. The first distinction is most

> tivity of "taller than" seem to be inherent constraints in the physical world This fact defines "taller than" as a transitive relation. The asymmetry and transi-

of preserving structure intrinsic representation. Representation is (purely) y cannot be simultaneously longer than x. It is transitive, because if x is longer metric and transitive. There are two quite different ways of achieving this result is to be represented by some other relation, it too must be functionally asymthan," or any other relation that is inherently asymmetric and transitive. than" (World E), "larger than" (World F), "brighter than," "more numerous representation of "taller than" would be intrinsic if it were modeled by "shorter relation is intrinsic to the relation itself rather than imposed from outside. The its represented relation. That is, the logical structure required of the representing intrinsic whenever a representing relation has the same inherent constraints as than y, and y is longer than z, then x must be longer than z. We call this method herent constraints. It is asymmetric, because if line x is longer than line y, then In World B, for example, the "longer than" relation seems to have the same in-It follows from our present definition of representation that if "taller than"

although it is possible for it to be either or both. Its ability to represent "taller straints on this representing relation. If x is arrow-connected to y, then y might connected to" represents "taller than," but there seem to be no inherent con structure the representing relation has, then, is imposed on it by the relation in tion is totally arbitrary and that of its represented relation is not. Whatever tion is (purely) extrinsic whenever the inherent structure of a representing rela-We call this method of preserving structure extrinsic representation. Representa imposed on it by requiring that it preserve the structure of its represented relation than" follows directly from this fact. Asymmetry and transitivity can be literally is arrow-connected to z, then x might be arrow-connected to z, or it might not be arrow-connected to x, or it might not. If x is arrow-connected to y, and yThus arrow-connectedness is not necessarily either asymmetric or transitive The situation is strikingly different in World G, however. Here, "is arrow

asymmetry is represented extrinsically. transitivity of the "taller than" relation is represented intrinsically, whereas its there is no reason why there could not be one from y to x as well. Thus the inherently asymmetric, however. If there is a path of arrows from x to y, ther x to y and another from y to z, then there must be a path from x to z. It is not to" relation is inherently transitive, because if there exists a path of arrows from sically and the other extrinsically. Not so obviously, both can be used in modeling mixed. Obviously, one relation in a given representation can be modeled intrinthe same relation. World H is an example of this. The "is arrow-path-connected There are two ways in which intrinsic and extrinsic representation can be

structure," a notion fraught with deep philosophical problems. After a moment's extrinsic representation. The caution is that it rests on the concept of "inherent reflection, it is seen that "inherent structure" is closely related to the philosophical A word of caution is necessary about the distinction between intrinsic and

see later, the distinction lies at the heart of a current psychological controversy notion of inherent structure are intuitively clear enough to be useful. Most of these are currently thought matrix (C), a multicomponent vector (D), a binary feature set (E), a list of classificational system, there is a template (A), a neural network (B), a digital easily recognizable types of representation for a diagonal line. Within the usual To demonstrate the flaw in this way of thinking, Fig. 9.3 shows seven standard

its objects, a'', b'', c'', d'', can also be considered part of a similar mapping function from the mental world, x'' = g(x'). Now we see that the objects of the mental model can also be expressed by a mapping function from the objects of the real world, x'' = g[f(x)] or x'' =a, b, c, and d and that those of the mental world are a', b', c', and d'. Because the mental it will be true if the mental model is an isomorphic (rather than homomorphic) representa will result in the same relations being preserved in the mental model as in the mental world h(x), where h is just the composite of functions g and f. Thus, h is the representational mapping from the real world to the mental model. Although it is not universally true that this f(x). Because the model of the mental world is also a representation of the mental world, from the real world objects to the mental world objects that could be expressed as x' =world is a representation of the real world, there exists a mapping function (correspondence) tion of the mental world. ²This idea can be demonstrated as follows. Suppose that the objects of the real world are

psychologists who postulate mental representations. irrelevant. His claims about the information available in the real world are still important for The fact that Gibson does not acknowledge the existence of mental representation is

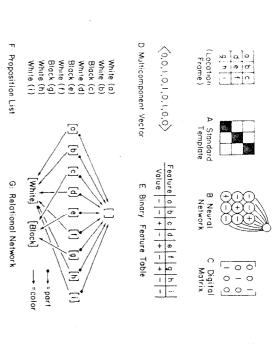

FIG. 9.3. Seven standard cognitive representations of a diagonal line. The letters a-i in Representations E, F, and G refer to the locations indicated in the Location Frame in the upper left corner. In Representation D, the vector components are in alphabetical order of the location-frame letters (a, b, c, ...).

to be different theories of representation. What are the differences, and are they meaningful for cognitive theory? They look different, and we talk about them differently. But these things may or may not reflect substantive differences at the level of cognitive theories of representation.

Let us examine them from the new view of representation. Each one consists of nine components, where each component represents a point (or, equivalently, a point's location) in the pattern. What dimensions are represented? Each representation contains information about the location and color of the individual points. In A, B, and C, location information is preserved by spatial location, in D by position in the vector, in E by identity of the feature, and in F and G by identity of the arguments of the relations. In A, color is represented by color, in B and E by "+" and "-", in C and D by "1" and "0" entries, and in F and G by the labels "white" and "black." In each case, then, color is a two-valued dimension, and location is a nine-valued dimension. The representation of both color and location is nominal inmost cases, although A, B, and C seem to contain more information about location. As argued earlier, one must consider the processes that operate on the representations to determine what information is actually included in the representation. As we see later, the processing assump-

tions for standard templates, neural networks, and digital matrices reveal that location is represented nominally.

If this is a reasonable analysis, all seven representations in Fig. 9.3 are informationally equivalent but not completely equivalent. That is, they differ only in the concrete way information is preserved, not in what information is preserved about their referents. This means that they are all models of the same cognitive theory. In fact, they all turn out to be models of standard template theory.

I have obviously taken some liberties in constructing these drawings. No one has ever (to my knowledge) proposed a feature theory quite like the one shown. But why not? It is against the rules of feature theories? If so, why? These are questions that must be answered in order to understand our theories properly. The pictures we draw must not be confused with the representational assumptions contained in the theory itself. We must see through the surface form of those pictures to the information they contain about the represented world. That is what cognitive theories of representation are all about.

Templates

Until recently, templates have been the perennial "straw men" of perceptual representation. Discussions by Neisser (1967) and Lindsay and Norman (1972) have succeeded in convincing a whole generation of cognitive psychologists that templates — whatever they are — are useless representations for pattern-recognition systems. Two developments have brought about a resurgence of interest in templates. One is the construct of "prototypes" in representing categories (Rosch, 1973; Chapter 2 of this volume). The other is recent work on image rotation (Cooper, 1975; Cooper & Shepard, 1973; Shepard & Metzler, 1971) and image scanning (Kosslyn, 1973; 1975a; Chapter 8 of this volume). Rightly or wrongly, these phenomena have been seen as possible evidence for the existence of template-like representations. In addition, templates seem to be good candidates for the kind of low-level visual information storage studied by Sperling (1960).

The construct of templates has been with us for a long time, but no one has ever really defined it properly. Perhaps the most common "definition" is to point to a figure that displays a digitized pattern overlapping to a certain extent with an input pattern (Neisser, 1967, p. 51; Lindsay & Norman, 1972, pp. 2–6). The figure and accompanying text provide the reader with an intuitive feel for how template matching systems work but no real definition of the representations on which they operate. Worse still, processing assumptions that are totally independent of representational assumptions (e.g., parallel matching) are often confused with the form of representation.

The basic problem in understanding the fundamental nature of templates is that they are displayed as *pictures* of the patterns they are intended to represent. These pictures have all the information in their referents, at least implicitly. The

template-picture has lines and angles plus properties like closedness and symmetry. It is not at all transparent to the nature of the underlying theory. Only when the operations performed on templates are considered do the assumptions about representation become clear.

Standard Templates. The simplest case is a standard template match without any "preprocessing operations" (Neisser, 1967). Consider what happens when a template match is performed. The template in memory is compared to the input pattern in a point-to-point fashion, where location determines the correspondence of points. For each pair of corresponding points that have the same color (both white or both black), a match is registered. If there are n locations, then the number of matches can vary from no points to all n points. This defines a similarity dimension with n+1 values for pairs of templates. It is used to classify patterns according to some decision strategy, usually of the best-fit variety.

There are two important things to notice about this process. First, no components are considered except individual points, and no dimensions are considered except location and color. Thus angles, lines, closedness, and all the rest of the information in the template-picture are irrelevant. They are not represented information, because there are no operations that define them or use them. Second, the matching process requires only information about the identity of locations and colors. It does not matter in the slightest whether one location is above, below, or close to another location, as long as it is matched to the corresponding point in the input pattern. In sum, both location and color are nominally represented dimensions.

Standard templates, then, are defined as follows. Templates are representations in which each pattern is composed of n points, and each point is defined by just two dimensional values: one from an n-valued, nominal dimension representing location and the other from a two-valued, nominal dimension representing color. Thus, all of the illustrations shown in Fig. 9.3 are surface variations (i.e., informationally equivalent models) of standard template theory when the usual processing operations are employed. Notice that many of the bizarre forms are far more revealing of the essence of templates than is the usual form.

Preprocessed Templates. The problems with standard templates are well known. Because they are position-, orientation-, and size-specific, trivial changes in these parameters of the input pattern have catastrophic consequences for classification performance. To correct these difficulties, Neisser (1967) suggested "preprocessing operations" to normalize (translate, rotate, dilate, and "clean up") the input pattern prior to matching. The extent to which such operations actually solve such problems is not at issue here. The important point is that

these preprocessing operations require a significant change in representational assumptions.

It is still true that points, locations, and colors are the basic kinds of information represented. But the representation of location cannot be nominal. In order to "fill in" a light point surrounded by black points, relations like "between" must be operationally defined. In a nominal representation of location, "filling in" operations could not be performed. Similarly, shifting a pattern x units in a given direction cannot be done with nominal representation of location. In fact, the usual preprocessing operations seem to require that location be represented at least intervally, because units of locational dimensions must be constant.

Similar changes could be made in the representation of color. The resolution of the color dimension could be greatly increased, and its values could be made ordinal or interval. Such information could be used to construct more powerful matching procedures that include partial matches for intermediate levels of grayness. In any case, the representational assumptions of preprocessed templates differ significantly from those of standard templates.

Hierarchical Templates. A slightly more deviant type of template theory is what might be called "hierarchical templates" or "minitemplates." The basic notion is that the components of a complex pattern might be a set of simpler templates rather than just a set of points. The simpler templates would then be defined by either even-simpler templates or by a set of individual points. Thus this representation is a hierarchy with individual points at the terminals. Such representations border on structural descriptions in that they have an articulated structure of higher-order parts.

The general nature of templates, then, rests largely on the kind of information represented: points, locations, and colors. There seems to be some agreement on color being represented as a nominal, two-valued dimension, but that could be relaxed. Note that the assumptions are actually of the sort that should be important for a cognitive theory of representation. Once the surface form is disregarded, templates are a fairly well-defined theory. Perhaps this is why template theory is so easily and frequently shown to be false. As we see later, most other purported theories are so vauge that they cannot really be tested.

Features

Feature representations were invented as an alternative to templates. As initially proposed, features were things like horizontal lines, angles, curves, and so forth. Since then, many additional features have been postulated for special purposes: closedness, complexity, wiggliness, and height of forehead, to name just a few. They are probably the most widely used form of representation. A large part of their popularity stems from their flexibility; anything can be a feature. This is

convenient to use to explain data, but it makes them inherently ill-defined as a simultaneously their greatest strength and greatest weakness. It makes them

of the relationships among them. seem to be binary features, multidimensional spaces, and hierarchical features. We consider the representational assumptions of each in turn and clarify some There are a number of feature theories in current use. The three most popular

Binary Features. Perhaps the most common type of feature theory is sets of binary features. Prominent examples include E.J. Gibson's (1969) distinctive feature theory of letters and Jacobson, Fant, and Halle's (1961) distinctive feature theory of phonemes.

complex decision strategies are sometimes used (e.g., Smith, Shoben, & Rips, same features as the memory representation of the pattern type. Other more employed rule is a 100% threshold, requiring that the input pattern have all the to classify the pattern according to some decision strategy. The most frequently the saliency of different features. The resulting similarity dimension is then used matches, although various weighting parameters can be introduced to reflect matching results for each feature. The simplest computation is the number of measure of similarity is computed according to a function that integrates the stored representation - i.e., both have the feature, or both fail to have it. Some each feature, a match is registered if the input pattern has the same value as the types, each one being defined by the outcomes of the same feature tests. For results of these tests are compared to a set of stored representations of pattern properties like having horizontal lines, being closed, and being symmetrical. The other for absence of the feature. (Precisely how this happens is seldom discussed.) in Gibson's theory, for example, letters are defined by presence or absence of Each test has two possible outcomes, one for presence of the feature and the feature tests are applied to an input pattern — either serially or simultaneously. Binary feature theories operate more or less as follows. A set of n operational

A more powerful representation is needed for representation of which lines are part of which angles, nor of how the lines are can represent a given pattern having three lines and three angles, there is no ships among patterns and their parts. For example, although a feature theory "is top-middle-connected to" Y. pattern recognition because of their poor modeling of structural interrelation-Some theorists came to reject both features and templates as representations for

representation of a pattern was the set of production rules required to generate of generative grammars (Narasimhan, 1969; Narasimhan & Reddy, 1967). The The initial attempts at structural description theories followed the formalisms

it from primitive patterns. The production rules specified the manner in which parts were to be combined into wholes. Since then, grammatical formalisms have largely disappeared, but the legacy of representing *n*-ary relations has remained. It is essentially the power of representing relations on more than single objects that differentiates structural descriptions from features.

Simple Structural Descriptions. Simple structural descriptions are closely related to hierarchical templates. The basic idea is that a pattern is defined by relationships among subpatterns. Each subpattern can be thought of as a minitemplate. The specified relationship among the minitemplates is satisfied by moving and turning the minitemplates until the proper relations hold. Each of the subpatterns, of course, could be either a primitive (usually, points or lines) or relationships among further subpatterns. Simple structural descriptions differ from hierarchical templates in that the relations among subpatterns are subject to variation. It is this variation in relationships that is represented by the structural relations in the representation.

In a structural description, each pattern is represented by a set of values for m n-ary relational dimensions. Each value of an n-ary dimension is a relation among n subpatterns. Because this is a rather complex concept, let us consider an example. The letter "T" might be defined in the following kind of structural description: "T" is the connection of the middle of a horizontal line to the top of a vertical line. This description actually contains three components: "T" contains a horizontal line, "T" contains a vertical line, and the horizontal line is middle-top-connected to the vertical line. The first two are binary relations between T and its subpatterns, and the third is a binary relation between the two subpatterns themselves. It is the third component that is important and distinguishes structural descriptions from feature theories.

that indirectly constrain how the horizontal and vertical lines can be arranged constructed unary relations. The usual solution is to add more unary relations status as representational objects. They are inextricably bound within the two second argument of the "contains" relation. The features of T then become the following features are added to the definition of T: "has an intersection," For example, many possible arrangements of the two lines are ruled out when feature theory, however, the horizontal and vertical lines do not have independent principle from representing the relations between T and the subpatterns. In a tions. Therefore, representing the relation between them is no different in "contains-a-vertical-line" and "contains-a-horizontal-line," both of which are the horizontal and vertical lines are independent object-elements in their descripfor feature theory. It is not a problem for structural description, because both familiar features in existing feature theories. But the last relation is a problem One simply defines two different unary relations by binding the two parts to the feature theory. The "contains" relations between T and its parts are no problem Consider how to translate the three components into unary relations for a

"has two right angles," "is open," and "is symmetrical." Despite these complex, higher-order features, the indirect constraints are seldom tight enough to rule out all illegal patterns. The only sure-fire feature would be something like "has-a-horizontal-line-whose-middle-is-connected-to-the-top-of-a-vertical-line." At this level of complexity, one might just as well have a feature called "looks-like-a-T."

The sure-fire solution for feature theory has the unfortunate side effect of proliferating represented relations. Suppose that there are just 10 basic subpatterns for a given class of patterns and 10 possible relations that might hold between any pair. The structural description theory would have 20 primitive elements, one for each subpattern and one for each relation. They would be combined in appropriate ways to define the patterns. The corresponding feature theory would require, in principle, 1000 features to have the same power. Each complex feature would be pairing of each of the 100 possible ordered pairs of basic subpatterns with each of the 10 possible relations. Thus, it may well be the case that there is always a feature theory that is informationally equivalent to a given structural description theory, but the latter is preferable on grounds of simplicity.

Augmented Structural Descriptions. One potential drawback to simple structural descriptions is that, like templates, their representations ultimately rely on just locations and colors of points. Although these primitives are combined in powerful ways into higher-order parts and patterns, every bit of information must be derived from them. The problem is that when higher-order parts are formed by relationships among component parts, the larger patterns frequently have "emergent properties" not defined for the components. For example, a line can be defined as a particular relationship among a set of points, but the line has properties like length and orientation that are not properties of the component properties like length and closedness that are not properties of the component lines.

An obvious solution to this problem is to augment simple structural descriptions with features for the higher-order patterns. The result is a hybrid of feature theory and structural descriptions that we call augmented structural descriptions. The general assumptions are that any pattern is represented both as a set of unary dimensional values and as a set of relationships among component parts. This provides the power necessary to represent emergent properties like those mentioned previously. Examples include the models of Palmer (1975a) and Winston (1975).

By this point, we have reached a type of "theory" that is so powerful that it no longer is any theory at all. Notice that there are virtually no constraints on what information can be represented. There can be any number of dimensions that can hold among any number of objects. The dimensions can represent any kind of information with any resolution and any uniqueness properties. In their

augmented structural description theory become more than an abstract frameof the class, however, can be tested. But one must do things like specify what dimensions are represented and how they are represented. Only then does an theory of perceptual representation as a general class. Particular examples most general form, then, augmented structural descriptions are an untestable work in which to construct particular theories.

assumptions required by prototype theories. that prototypes of some sort play a critical role in human categorization is comexistence of prototypes for natural categories like colors and animals as well as pelling. The question that concerns us here is the nature of the representational for artificial categories like dot patterns and schematic drawings. The evidence (Rosch, 1973, 1977; Chapter 2 of this volume). She has demonstrated the in large part to the seminal work of Eleanor Rosch on categorical prototypes prototypes in cognitive representation and processing. This development is due A great deal of interest has recently been generated about the possible role of

be only "template-like." For example, in a recent book on pattern recognition informed that templates are wrong, however, prototypes are usually thought to class. Because everyone who has read an introductory text in cognition has been and because they are associated with particular examples of the category. The some sort. This is partly because prototypes are frequently discussed as "images" portance of prototypes: (Reed, 1973), we find the following discussion of results demonstrating the inthat templates are universally described as "prototypical" examples of their association between prototypes and templates is further strengthened by the fact The most common belief about prototypes is that they must be templates of

represents the central tendency, is determined by the mean value of each to other patterns. Instead, a prototype consists of features and when it template in which the amount of overlap is used to judge its similarity results also support a template theory. But a prototype is not an unanalyzed feature when the mean is calculated from all patterns in the category Insofar as a prototype may be thought of as a type of template, these

and yet they are not templates but features. In what sense are they like templates and in what sense like features? Are they necessarily related to these concepts This passage illustrates the confusion about prototypes; they are template-like

> on the basis of degree of similarity. The most common classification rule is of or even continuous. A decision strategy is used to assign the pattern to a category and each categorical prototype. The similarity is assumed to be highly resolved the prototypes. A measure of similarity is computed between the input pattern are constructed, the input pattern is represented along the same dimensions as the best-fit variety such that each pattern is classified into one-and-only-one typical" or the "ideal" instance of the category. However these representations are assumed to be highly specific in the sense that they approximate the "most tion operates. There are categorical representations stored in memory. These Let us begin by considering how a prototype theory of perceptual classifica

would be classified at all, or some instances would be classified into many catewould result in unacceptable categorization performance. Either too few instances all follow from the single assumption that categorical representations are highly gories. Thus the basic assumptions of prototype process-models of classification dimension with low resolution and/or using strict 100% threshold decision criteria That is, if the categorical representation is highly specific, then using a similarity classification. Note that both (2) and (3) are pragmatically determined by (1). similarity dimension is highly resolved; and (3) a best-fit criterion is used for prototype theories are: (1) the stored representations are highly specific; (2) the measures are then used to categorize the pattern. The major elaborations for represented and compared to stored representations for similarity. The similarity The general form of this process is the same as before. The input pattern is

to within-category variation. A prototype representation is one that has relatively categories. Now it becomes clear that the specificity of prototypes is with respect high resolution for dimensions of information that vary within the category. that vary within the category. They represent only dimensions that vary across true, invariant-attribute representations of categories cannot represent dimensions that each instance is completely and equally consistent with it. For this to be The essence of these theories is a very general representation of categories such in opposition to the "invariant attribute" approach (e.g., E.J. Gibson, 1969). representation highly specific? The prototype approach is properly considered Let us consider this assumption more carefully. In what sense is the categorical

is the usual prototype approach - the prototypical prototype approach, if you other extreme is the standard invariant attributes approach, in which no aspect will - in which every aspect of within-category variation is represented. At the which differ in their representation of within-category variation. At one extreme namely, that underlying the dichotomy is a broad range of possible theories approaches are dichotomous. The present analysis leads to a different view -The standard view seems to be that the prototype and invariant-attribute

Nothing has yet been said about exactly what the dimensions are nor just how they are represented. This is because prototype theories as a general class do not require such assumptions except when they are particularized for a given category. Certainly, standard templates satisfy the specificity constraint, but they are not the only kind of theory that does so. Binary feature theories can also represent within-category variations, provided there are sufficiently many such features (e.g., Smith, Shoben, & Rips, 1974). In fact, any reasonable theory of perceptual representation in general will have to be consistent with the notion of prototypes, bécause it will have to have the capability of representing highly specific instances. If not, the theory would never be able to account for how people can distinguish their own house from other houses or their own dog from otherdogs. In short, prototypes are a construct of categorical representations, not of representations in general. As a class, they are equally compatible with virtually any theory that can represent specific instances.

Shepard's Principles of Isomorphism

Roger Shepard has discussed the nature of possible forms of isomorphism that might hold between the real world and people's internal representations of that world (Shepard & Chipman, 1970; Shepard, 1975). In particular, he has distinguished between what he calls "first-order" and "second-order" isomorphism. These concepts have gained wide currency within cognitive psychology and are believed to have implications for the field. I discuss the nature and importance of Shepard's proposals because they seem to be frequently misunderstood. First, I formulate them within the new framework of representation to clarify them. Then I argue that second-order isomorphism, in its most general sense, is not a theory of representation but a definition. Finally, I argue that the distinction between first- and second-order isomorphism is irrelevant for cognitive psychology.

First-Order Isomorphism. Simply stated, first-order isomorphism is a concept of mental representation in which the properties of real-world objects are retained in the internal representation of those objects. To use Shepard's original examples (Shepard & Chipman, 1970), in a first-order isomorphism, the representations of green things must be themselves green, and those of square things must be themselves square. Shepard rejects this notion of the correspondence between the real world and the mental world by arguing that it is physiologically absurd to suppose that the internal representations of green things are themselves green and that it is unnecessary and implausible to suppose that those of square

things are themselves square. In a later paper, Shepard (1975) refers to this as concrete first-order isomorphism.

Translating this concept into the present framework is straightforward. A representation is concretely first-order isomorphic to its referent if the unary relations (properties) of the represented objects are preserved by the physically equivalent unary relations (properties) of the representing objects. Thus, greenness is reflected by greenness and squareness by squareness. The most sensible interpretation for the name of this concept is that "first-order" signifies that relations on individual objects (properties) constitute the information of interest and that "concrete" signifies that the corresponding relations must be physically the same.

Shepard distinguishes concrete from abstract first-order isomorphism in a later paper (Shepard, 1975). His example is that an abstract first-order isomorphism would hold if the internal representation of a square contained four parts, each of which correspondended to a corner of the square. Unfortunately, the example is ambiguous, and Shepard does not discuss it fully enough for the reader to know exactly what he intended.

The "abstract" version of our previous definition should be that a representation is abstractly first-order isomorphic if the unary relations of the represented objects are preserved by functionally (or operationally) equivalent unary relations of the representing objects. This example is then interpreted as follows. One of the properties of squares is that they have corners as parts, four of them in fact. This is reflected in the representing world by the square-representation having corner-representations as parts, four of them in fact. The isomorphism is not concrete, because "having-four-corners-as-parts" is not physically equivalent to "having-four-corner-representations-as-parts." In the special case where the corner-representations are themselves corners, concrete first-order isomorphism would hold.

In the other interpretation, we consider binary relations within each world rather than unary ones. The square has a relationship to each of its corners: Namely, the corners are "part of" the square. Similarly, the square-representation has a relationship to each of its corner-representations: Namely, the corner-representations are "part of" the square-representation. Now it seems that the represented binary relation is physically the same as the representing binary relation. In other words, the example might also be considered an instance of concrete second-order isomorphism by simple extension of our previous definition. I am not sure that Shepard actually meant to convey either of these concepts, but within the present framework, they are both possible.

Second-Order Isomorphism. Shepard's alternative to first-order isomorphism is second-order isomorphism. His example is that the internal representation of a square need not be itself square, but — whatever it is — it must be functionally more similar to a rectangle than to a green flash or the taste of persimmon

(Shepard & Chipman, 1970). It is important to realize that more than one thing has changed from the initial example of concrete first-order isomorphism. As the name implies, one change is from talking about the correspondence between properties of single objects to talking about that between relationships among more than one object. One would think this is the important change, but it is not.

Consider the binary relation "greener than" in contrast to the unary relation "green." First-order isomorphism implies that if an external object is green, its internal representation is also green. If second-orderness is the essence of second-order isomorphism, then replacing "green" with "greener than" relationships should yield an example of second-order isomorphism. Thus, if object A is greener than object B, then the representation of A should be greener than the representation of B. The only constraint that has been lifted is that the properties of individual objects in the external and internal worlds need not be identical. That is, the representation of A need not be itself green (it might be blue-green or even blue), but it still must be greener than the representation of B.

Now we see that the other change is from physical sameness to functional sameness. This is the important one. Because of it, external greenness need not be like internal greenness in any physical sense but only in a functional sense. That is, when the greenness of an external object changes, there is some corresponding change in the internal object that may be nothing like changes in greenness. This functional correspondences is what effectively decouples the internal and external world in terms of resemblances. Shepard's terminology is unfortunate, because it emphasizes the wrong change. It would be better to call first-order isomorphism "physical isomorphism" and second-order isomorphism "functional isomorphism," where either can hold for properties or any higher-order relations.

Second-Order Isomorphism: Theory or Definition? Regardless of what one chooses to call it, the basic concept referred to as second-order isomorphism can be defined as follows. A representation is second-order isomorphic to its referent world if the similarity of represented objects is functionally reflected by the similarity of the corresponding representing objects. What makes this difficult to pin down is the construct of similarity in both the external and internal worlds. Whether second-order isomorphism is a theory (or class of theories) of cognitive representation or just a definition depends on how broadly the concept of similarity is interpreted.

In its most general sense, similarity is a binary dimension containing at least two values. That is, the crudest sort of similarity is a one-bit classification into "same" or "different" relations. Inserting this into the previous definition we have: A representation is second-order isomorphic to its referent world if a binary dimension containing at least two values is functionally reflected by a binary dimension containing at least two values for the corresponding representing objects. This must be true even for purely nominal representations, because they preserve same/different binary relations. Thus, verbal labels for objects

satisfy this broad interpretation of second-order isomorphism. (It is perhaps worth noting at this point that verbal descriptions constructed by selecting one label from each of n sets of possible descriptions are no different in principle from nominal feature sets of the kind discussed earlier. Both are purely nominal, unary dimensions in which only same/different relationships are meaningful.)

I suspect Shepard's intention was to convey a more restricted concept of similarity, however. The intuitive notion of similarity connotes a highly resolved or even continuous dimension to most psychologists. With this notion of similarity, second-order isomorphism becomes more specific. It rules out, for example, representations containing only a few nominal dimensions. If the concept of second-order isomorphism is further required to hold within a single dimension, then it rules out all representations with low resolution of their dimensions (e.g., standard binary features). In any case, the status of second-order isomorphism as a theory or a definition of representation is unclear as long as the construct of similarity is left undefined.

Distinguishing First- from Second-Order Isomorphism. As Shepard has pointed out, all first-order isomorphisms are necessarily second-order isomorphisms, but the reverse is not true. The present question is whether cognitive psychology can hope to distinguish between them given the methods of experimental, behavioral psychology.

Suppose that there are two models of cognitive representation, one first-order and one second-order isomorph of the external world. The first-order model specifies that external greenness is modeled by internal greenness and external squareness by internal squareness. The second-order model specifies that external greenness is modeled by internal squareness and external squareness by internal greenness. There are two points to be made. First, a second-order isomorphism cannot be distinguished from a first-order one without "looking inside the head" at the actual representing world. Moreover, just looking inside the head will not be sufficient to determine whether the representation is first-or second-order isomorphic to the world, because both models are characterized by just internal-greenness and internal-squareness. In order to test the two models, one must have access to the mapping function from the outside world. Does internal greenness correspond to external greenness or external squareness? Both looking inside the head and determining the mapping function are tasks for physiological psychology, not cognitive psychology.

The second point is that a second-order isomorphism is not necessarily any more plausible than a first-order isomorphism in physiological terms. The present example illustrates this obvious fact, assuming that no part of the nervous system is actually green or that, if it is, this fact is irrelevant to how it represents information. The only thing that matters is whether the postulated physical properties of the internal representation are consistent with the known physical properties of the nervous system. One can try to figure out what dimensions

could possibly be represented as first-order isomorphisms, but this is armchair speculation for cognitive psychologists. More than anything else, the notion of second-order isomorphism (in its general interpretation) is simply a philosophical comfort to cognitive psychologists, because it provides a justification for not worrying about precisely those issues involved in first-order isomorphism.

The Propositional/Analog Controversy

One of the most holly debated issues of cognition these days is whether representations are "propositional" or "analog" in nature (e.g., Pylyshyn, 1973, 1975; Kosslyn, 1975b; Kosslyn & Pomerantz, 1977; Palmer, 1975b). The arguments began with the appearance of Pylyshyn's (1973) influential paper attacking the "picture metaphor" of visual imagery. The arguments seem to have spread to perceptually related representations in general. The terms "propositional" and "analog" have become emotionally charged buzz words capable of provoking arguments almost instantaneously.

Naturally, the entire controversy rests on the presupposition that propositional and analog representations are fundamentally opposed in some way that is relevant to cognitive theories and/or experiments. Whether this is true or not depends on how the terms are defined and what one takes to be the domain of cognitive psychology. In the following subsection, I define propositional representations and discuss their implications. Then I discuss a few of the concepts of analog representation that seem to be in current use. I also suggest a new way of looking at the notions of propositional and analog representation based on the distinction between intrinsic and extrinsic representation. To anticipate the conclusion, it turns out that propositions and analogs are fundamentally opposed but in ways that are not relevant for cognitive psychology. Further, I suggest that the reason for the controversy lies in differences between the two camps in terms of theoretical goals and styles.

Propositional Representation. The fundamental nature of propositional representation is quite simple. Recall the definition of representation: A world, X, is a representation of another world, Y, if at least some of the relations among objects of X are preserved by relations among objects of Y. This definition requires that any representation must have "object elements" to correspond to the represented objects. It might also have "relational elements" that model the relations (e.g., the arrows of World G in Fig. 9.1) or it might not (e.g., Worlds B.-F in Fig. 9.1). Propositional representations are simply those in which there exist relational elements that model relations by virtue of themselves being related to object elements. The result is that relationships among n object elements cannot be determined simply by examining those n elements. One must determine them by examining their relationships to the additional relational elements.

notational devices (e.g., Schank, 1972; Leeuwenberg, 1971). looking propositional representations in current use, including some with bizzarre or "1" rather than by a "-" or "0". In fact, there are many quite differentof the object elements by virtue of their being row-column connected by "+" relation is usually a column (or row). The relational elements are "predicated" object is usually a row (or column) and the element representing the unary propositionally. In a feature table, for example, the element representing the networks do also. Somewhat surprisingly, binary features are usually expressed elements and devices for specifying ordered-connectedness to them. Relational specifies a relationship between the ball and the table that can only be understood Other kinds of propositional representations have the same basic properties. by virtue of their syntactic relationships to the relational construction "is under." to objects are related in syntactically ordered strings through relational words Lists of sentences in predicate calculus notation contain explicit relational (verbs, prepositions, and the like). The sentence, "The ball is under the table," Language is the paradigm case of propositional representation. Words referring

Analog Representations. The problem in attempting to characterize analog representations is that they seem to be different things to different people. I briefly characterize three notions that seem to be used most frequently.

The clearest and most obvious interpretation is that "analog" representations are those in which dimensions are continuous rather than discrete. The intended contrast is between analog and digital computers. Analog computers represent information in a physical dimension that, for all functional purposes, varies continuously (voltage). Digital computers do so in discrete, quantized units (bits). Although the continuous/discrete distinction may be of theoretical interest, it is not a question that seems to be answerable given state-of-the-art behavioral techniques. The cruder question of high versus low resolution within a given dimension is answerable, but having high resolution is not the same thing as being continuous.

The other two meanings for "analog" are both related to the visual imagery controversy. The claim is that visual images are, in some sense, "spatial" (Kosslyn, 1975a; Chapter 8 of this volume). The weaker version of this claim is that visual images preserve spatial information about that which they represent. For example, if object A is above object B in the represented world, then the representing world — whatever it is — will have objects A and B in some relationship that functionally corresponds to aboveness in the external world. Thus the weak spatial claim is equivalent to proposing that the image represents spatial dimensions in some fashion. This is a very mild and sensible position, one that is not opposed to propositional representation in any way.

The stronger spatial claim is, I suspect, the more usual one. In this interpretation, spatial information is not only preserved, but it is preserved (1) in a spatial medium, and (2) in such a way that the image resembles that which it represents.

is inverted) the representation of B in the image. Although this is not a physicindistinguishable from informationally equivalent representations that are no nevertheless. Like all proposals of first-order isomorphism, it is functionally logically absurd type of first-order isomorphism, it is a first-order isomorphism that the representation of A is physically above (or perhaps below, if the image For example, if A is above B in the external world, the strong claim would be first-order isomorphic.

put analog and propositional representations in opposition to one another isomorphism but a stronger one that functional isomorphism. Moreover, it does what most "analog" theorists have in mind. It is a weaker claim than physical anyone define "analog" in quite the way I now suggest, I suspect it is close to Intrinsic Versus Extrinsic Representation. Although I have never heard

with extrinsic methods. Let us see how this proposal ties in with what has been analog representation with intrinsic methods and propositional representations sented world. The propositional/analog controversy makes sense if we associate build the necessary structure into the system explicitly to conform to the repre formation using a relation or dimension that has no inherent structure, but to or dimension chosen. The extrinsic method was to model the represented intion of logical structure is a "natural" consequence of the representing relation same inherent structure as that which it represents. In such cases, the preservarelation or dimension by using a representing relation or dimension that has the two different approaches. The intrinsic method was to model a represented discussed so far. Recall that in discussing methods of preserving relational structure, we noted

informational correspondence with the represented world. solely by virtue of the extrinsic constraints placed on it by the truth-preserving sented. Thus, whatever structure there is in a propositional representation exists elements places no constraints whatsoever on the nature of the relations repre element in any fashion. Hooking up object elements by relations to relational elements in representing relations is that propositions are extrinsic representations with surface manifestations. At a deeper level, the significance of using relational The reason is that any object can, in principle, be connected to any relational The previous discussion of propositional representation was mainly concerned

as a representation, the constraints are external to the descriptive world. By statements, not both descriptions could be used. Thus, if descriptions are to serve between B and A in the world. But if one is constrained to make only true precludes contradiction with fact. One can say, for example, "A is above B," and as "descriptive" and "interpreted" (Pylyshyn, 1973). The essence of a descripdefinition, then, descriptions are extrinsic representations. "B is above A." although not both descriptions could be true of the relationship tion is that it can be either true or false. There is nothing about descriptions that This fact is closely related to characterizations of propositional representations

> sentation exists by virtue of the inherent constraints within the representing world itself, without reference to the represented world. relations they can model. Thus, whatever structure is present in an analog reprerelations is inherent and therefore determines completely the kind of represented representations are necessarily intrinsic, because the structure of the representing by relationships among sets of the corresponding representing objects. These senting objects, and relationships among sets of represented objects are modeled of individual represented objects are modeled by properties of individual repreelements - i.e., nonpropositional representations. In such cases, the properties Analog representations are now seen to be those that contain no relational

isomorphic to its represented world. Thus there is a strict hierarchy of isomorphnaturally and functionally isomorphic to its represented world. Any representamorphism the most abstract. isms in which physical isomorphism is the most concrete and functional isois functionally isomorphic is not necessarily either naturally or physically physically isomorphic, to its represented world. Finally, any representation that tion that is naturally isomorphic is necessarily functionally isomorphic, but not In general, any representation that is physically isomorphic is necessarily both representations are functional isomorphisms but not natural isomorphisms. regardless of whether it is done by intrinsic or extrinsic means. Thus propositional ism, because the latter requires only a correspondence that preserves structure, calls it, this concept is a stronger claim than functional (second-order) isomorphpreserved by the nature of corresponding relations themselves. Whatever one might call this concept "natural isomorphism" to emphasize that structure is same is precisely that they have the same inherent structural constraints. We senting relations to be physically the same in a more abstract sense. In the present suppose we relax the strict interpretation of physical sameness to allow represic), because the same relations must have the same inherent structure in both sented relations in a physical sense. Any physical isomorphism is analog (intrinframework, the sense in which representing and represented relations are the worlds, provided their operational definitions are constant across worlds. Now, by virtue of the representing relations being themselves the same as their repreorder) isomorphisms. Recall that physical isomorphisms preserve information of isomorphism somewhere between physical (first-order) and functional (second Another way to view the nature of analog representation is in terms of a form

of "descriptive" versus "nondescriptive" or "interpreted" versus "noninterpreted" the propositions and analogs on the basis of intuitive notions about the properties propositional/analog controversy, is it relevant to and resolvable by cognitive and extrinsic representation is actually the fundamental issue underlying the representations. It has been my experience that such experiments are never psychology? One can attempt to construct experiments to distinguish between Relevance to Cognitive Psychology. If the distinction between intrinsic

convincing. Usually they are based on a simplistic notion of how the alternative type of theory might operate (see Kosslyn & Pomerantz, 1977, for some examples). Although such experiments may succeed in showing that analog-theory-X predicts better than propositional-theory-Y, the results do not seem to generalize beyond the particular examples.

The most compelling reason to believe that analog and propositional representations are not distinguishably different requires no experiments at all. Assuming that the intrinsic/extrinsic distinction is the fundamental issue, the answer to the controversy rests on the inherent nature of the representing relations and their relationship to the inherent nature of the corresponding represented relations. I see no way this can be determined without "looking inside the head." The concept of the inherent nature of representing relations concerns the physical medium that caries information. It is an abstract question about their physical nature, but one that concerns the physical medium nevertheless. Therefore, resolving the controversy over whether mental representation is analog or propositional is a task beyond the scope of cognitive psychology. It should be relegated to physiological psychologists, whose job it is to figure out the physical nature of inside-the-head and to determine its correspondence to outside-the-head.4

Approaches to Cognitive Models. There remains the interesting question of why the controversy arose in the first place. The answer provides some insights into different approaches to modeling in cognitive psychology.

There are two camps involved in the controversy. By and large, they divide cleanly in that proponents of the propositional view construct models by writing computer simulations, whereas proponents of the analog view do so by formulating analogies to known physical or formal systems. [Kosslyn is an exception, because he first worked by analogy (Kosslyn, 1973, 1975a; Kosslyn & Pomerantz, 1977) but has since simulated this analogy (Chapter 8 of this volume).] According to the analysis given here, this division is no accident.

As Weizenbaum (1976) has pointed out, computers are systems in which the programmer is freed from the constraints of the physical world. He or she works in the domain of "possible worlds" that can be constructed within the computer. Therefore, when a program is intended to model something else, the programmer needs to know everything about those aspects of the modeled world that are of interest in order to simulate them. In the most general symbolic languages, virtually nothing can be hidden in implicit structure, because in the domain of possible computer-worlds, there is no structure in which it can be hidden. Thus, if a computer-modeled relation is transitive or connected, it is because either the programmer or something in the program makes it have these properties. Any unspecified aspect is "magic" until it can be spelled out precisely. Once the behavior of the simulated world is known to the required level of analysis, it can be simulated. Being able to predict new things not specifically built into the programs is largely an accidental byproduct of constructing very complex programs. There is little or no intent to predict.

minimality, and the triangle inequality (see Tversky, 1977; Chapter 4 of this been tested only recently, more than a decade after the analogy gained popularity. of a space. In addition, similarity automatically has properties of symmetry, structural correspondences. In the spatial analogy, all of the dimensional features the fact that the assumptions underlying the similarity-as-distance analogy have volume). That many of these structural properties are hidden is evidenced by automatically have mutually exclusive values, because this is inherent in the axes all but the mark of a clever theorist who has recognized at least some of the is built into the model "accidentally." Of course, it is not really an accident at sional space and similarity as distances between points, a great deal of structure sional spaces. If psychological concepts are conceived as points in a multidimencontrol. A good example of modeling by analogy is the notion of multidimengous system the better. This structure provides a rich base of possible future sense, the more structure that is hidden in the inherent constraints of the analoof actual worlds that nearly always contain a great deal of structure. In some predictions from aspects of the system over which the modeler has no direct Modeling by analogy is quite different. The analogizer works in the domain

In short, computer modelers and systematic analogizers differ in the amount of structure they choose to have in their modeling medium. Computer modelers use an exceptionally flexible, unstructured medium. As a result, most structure must be built in explicitly to correspond to that of the modeled system. Analogizers work by choosing from among many rigid, highly structured media, each of which has constraints independent of its potential as a model of something else. It is not too surprising, then, that propositional models were developed by those who work with computers and that analog models were developed by the representing medium is precisely the difference between propositional (extrinsic) and analog (intrinsic) approaches to representation.

⁴¹t should be emphasized that the argument is that analog representations are indistinguishable from propositional ones because they can be informationally equivalent as representations. It is possible that they differ in some nonrepresentational way that makes one preferable to the other. Perhaps testable differences exist in processing operations, for example. Whether this is true or not depends on the outcome of a rigorous analysis of the fundamental properties of processing operations. I suspect that such an analysis will yield a result parallel to the present one. That is, given that some operation has certain performance characteristics, it might be that these characteristics are a necessary consequence of the physical operation (i.e., intrinsic to the operation). If so, intrinsic and extrinsic methods of modeling performance characteristics are just as indistinguishable as intrinsic and extrinsic methods of preserving information. There are also other grounds for preferring one type of theory over another, such as parsimony, simplicity, and other pragmatic or esthetic considerations.

CONCLUSION

sentation, we need a deeper understanding of our theories. nature. If we are to make significant progress on the nature of cognitive repreuntrue. Our understanding of the current concepts in representation is based of that representation. The view presented in this chapter indicates this to be containing "thing" that is operated upon by processes. I used to believe that if supposed. Within psychology at least, it has been associated with an informationlargely on superficial trappings that have little to do with their fundamental I was looking at that "thing" in a diagram or illustration, then I knew the nature Representation is a complex and elusive concept, much more so than is generally

tricately woven into the fabric of representation than is usually acknowledged. partly dependent on them. In general, however, operations are much more independent of representational assumptions and other aspects that are only from processing. There are many aspects of processing that are entirely inprocesses that use it. This is not to say that representation is indistinguishable is, one must first consider its functional information content as defined by those there actually is. To determine what the representational nature of the "thing" that much of the information that seems to be there is not really there at all define the information it contains. Considering those operations may reveal Conversely, it may turn out that much information that does not seem to be tional nature of this "thing" cannot be dissociated from the operations that One aspect of this deeper understanding is the realization that the representa-

More than anything else, it is what representation is all about. between represented and representing worlds should not be underestimated how similar they may seem on the surface. The importance of the correspondence provide views of the same world are not representationally equivalent, no matter presents of the represented world. Representations that provide the same view of important sense in which the nature of a representation is simply the view it it must preserve at least some information about its referent world. There is an the same world are at least informationally equivalent. Representations that the world it represents. In order for a "thing" to be a representation of any sort, Once the information content has been discovered, it must be related back to

sentational assumptions that define the theory it embodies that allows us to see through the "thing" we find in illustrations to the repretheory concerns information, not the medium used to carry it. It is this last step beyond the scope of cognitive theories. The proper level of discourse for cognitive of representation is what information it preserves about the representing world must be disregarded. In other words, the only thing that matters about the model and related to the represented world, all other aspects of the representing world standing our models of representation. Once the information has been discovered Issues that pertain to any physical aspects of the representing world are simply For the purposes of cognitive psychology, there is yet another step in under-

> we can solve them more quickly. understand the problems involved in cognitive representation properly, perhaps previously obscure and to clarify things that were previously confused. Once we issues from irrelevant ones and to see the relationships among our models and inadequate. As a result, we lack the insight that allows us to separate relevant concepts currently used to talk about representation are seriously confused and without some larger, metatheoretical framework in which to view them. The cannot properly understand our theories and models of cognitive representation framework I believe is necessary. It has helped me to notice things that were theories in a clear and systematic way. I have attempted to provide the sort of Perhaps the most general lesson to be learned from our discussions is that we

ACKNOWLEDGMENTS

Most of all, I thank Eleanor Rosch for her constant encouragement; without it Elizabeth Bates for their helpful comments on earlier versions of this chapter. I would like to thank Amos Tversky, Donald Norman, Zenon Pylyshyn, and I would have given up on this project long ago.
